Supporting Information

ABSTRACT: We report on the first partially interpenetrated metal–organic framework (MOF) with NbO topology for its ability to separate methane from carbon dioxide and permanently sequester the greenhouse gas CO2. The MOF, Cu2(pbpta) (H4pbpta = 4,4′,4″,4‴-(1,4-phenylenbis(pyridine-4,2-6-triyl))-tetra-benzoic acid), crystallizes in the monoclinic C2/m space group and has a 2537 m2/g Brunauer, Emmett and Teller surface area with an 1.06 cm3/g pore volume. The MOF exhibits selective adsorption of CO2 over CH4 as well as that of C2H6 and C2H4 over CH4. Cu2(pbpta) additionally shows excellent catalytic efficacy for the cycloaddition reaction of CO2 with epoxides to produce industrially important cyclic carbonates using solvent-free conditions.

INTRODUCTION

Energy focus over the past decade has adjusted to explore and utilize natural gas from reserves and landfills because it remains competitive with cleaner energy alternatives. Methane, the primary component in natural gas and landfill gas, is many times fouled with other hydrocarbons and unwanted species such as CO2, N2, H2S, and water. Production requires fuel enriching processes to remove unwanted gases primarily composed of CO2. Cryogenic distillation and pressure swing adsorption (PSA) methods have been used for separating equal and unequal volumes of CH4/CO2 from landfills and wells.1,2 The distillation techniques suffer from high operating cost, while PSA techniques demand adsorbents with high CO2 capacity and selectivity.3–5 Therefore, alternative methods are under development which show high separation capabilities to enrich methane. Furthermore, utilization of the CO2 captured after methane enrichment needs attention as it can serve as a feedstock for various processes. Here, research efforts are devoted to enrich methane stocks and convert CO2 into high-value added chemicals to truly remove it from the atmosphere and offset operational costs.

Beneficial catalysts that make use of CO2 as the C1 source are in dire need to replace expensive carbon capture and storage technologies. Numerous homogeneous catalysts using d8–d10 transitions metals have been shown to be useful in transforming CO2 into value-added chemicals.6,12 Whereas homogeneous catalysts offer many advantages, heterogeneous catalysts can be easily separated from the end products, thus offering the opportunity to continuously recycle the catalysts and offset initial costs. Where metals and metal nanoparticles participate as catalysts and cocatalysts, CO2 diffusion to these active sites may require extreme conditions. This can be alleviated using porous materials with a high affinity for CO2 at ambient conditions.

Thus, in order to address the aforementioned issue of methane enrichment from CO2 and utilize the captured CO2 through transformation into industrially relevant products, multifunctional material platforms are needed. Many porous materials have been explored in this direction which can accomplish the task of both separation and acting as a catalyst to offset CO2. These materials include zeolites, covalent organic frameworks (COFs), and metal–organic frameworks (MOFs).7–16

MOFs are one of the most promising classes of porous materials due to their high surface area, tunable pore sizes and geometries, and accessible functionality sites, whereby they...
Crystal Growth & Design

continue to be useful for gas sorption, separation, and catalysis. Many MOFs exhibit high surface areas, but the large pores and void spaces are not necessarily useful for low pressure adsorption of CO2. Therefore, techniques to reduce this free space and improve CO2 adsorption at low pressure have been tested through postsynthetic modification on the ligands or metal clusters, and by interpenetration or catenation in the frameworks. Interpenetration is beneficial for many MOFs as shown with improvements in the material’s robustness, stepwise gas adsorption, and selective adsorption. On a very rare instance, partial interpenetration has occurred in MOFs which can reduce the free space as observed in NOTT-202 and MUF-9. This may not be as uncommon as traditionally thought as there is evidence of MOFs changing their degrees of interpenetration when induced by pressure and desolvation, whereby high quality X-ray diffraction techniques have been used to observe this phenomena. The selective adsorption of CO2 is paramount for the development of various catalytic MOFs, which can actively participate in CO2 transformation reactions to use it as a C2 building block. Research efforts have found that CO2 occupies a position near unsaturated metal centers (UMCs) in MOFs at low pressure. This high interaction between CO2 and the UMC has led to high isosteric heats of adsorption (Qst), which is useful for the development of various catalytic materials for CO2 fixation reactions. Therefore, for the effective separation and fixation of CO2 we synthesized Cu2(pbpta), a partially interpenetrated MOF with NbO topology, examined its adsorption capabilities, and carried out cycloaddition reactions whereby the unsaturated Cu(II) actively participates in the formation of cyclic carbonates from solvent-free reactions.

## Experimental Section

**Materials and Methods.** All reagents and solvents were purchased from commercial sources and used as received. Powder X-ray diffraction (PXRD) data were collected at room temperature using a Bruker D8 Advance theta-2theta diffractometer with copper radiation (Cu Kα, λ = 1.5406 Å) and a secondary monochromator operating at 40 kV and 40 mA, whereby samples were measured between 3° and 50° at 0.5 s/step and step size of 0.05°. Single crystal X-ray diffraction data were collected using synchrotron radiation (λ = 0.41328 Å) at the Advanced Photon Source Beamline 15-ID-B of Argonne National Lab, Argonne, IL. Infrared spectra measurements from 4000 to 400 cm\(^{-1}\) were taken on a PerkinElmer FT-IR Spectrometer Spectrum Two (UATR Two) with 4 cm\(^{-1}\) resolution. A TA Instruments TGA Q50 was used to record thermal gravimetric analysis (TGA) data from room temperature to 600 °C at a rate of 10 °C/min. A Varian Unity Inova 400 spectrometer NMR was used to measure \(^1\)H NMR. Gas adsorption measurements were performed using a Micromeritics ASAP 2020 surface area analyzer to collect \(N\)2 (surface area measurement at 77 K), CO2, CH4, C2H6, and C3H8 isotherms at 273 and 298 K.

**Synthesis of 2,6-Di-p-tolyl-4-(2,6-di-p-tolylylpyrin-4-yl)phenylpyridine.** It was synthesized similarly as reported previously by Yang et al. \(^13\) Yield: 78.6%. \(^1\)H NMR (CDCl3, 400 MHz, ppm) δ: 2.46 (s, 12 H), 8.18 (d, 8 H), 7.95 (s, 8 H), 7.36 (d, 8 H).

**Synthesis of 4,4′,4″-((1,4-Phenylenebis(pyridine-4,2,6-triyl))-tetrabenzoic Acid (H4pbpta).** The reagent 2,6-di-p-tolyl-4-(2,6-di-p-tolylylpyrin-4-yl)phenylpyridine (1.0 g, 1.69 mmol) was added slowly to HNO3 (8 mL, 4 N) in a Teflon lined autoclave and heated to 180 °C for 48 h. After cooling, the reaction mixture was thoroughly washed with distilled water and purified by flash chromatography using an ethyl acetate/methanol (1/2 v/v) eluent. Yield: 74.2%. \(^1\)H NMR (DMSO, 400 MHz, ppm) δ: 8.01 (d, 4 H), 8.11 (d, 8 H), 8.30 (s, 4 H), 8.46 (d, 8 H). FT-IR (cm\(^{-1}\)): ν = 3015 (w, br.), 1682 (s), 1598 (m), 1573 (w), 1421 (m), 1280 (s), 1112 (m), 1015 (m), 861 (m), 775 (s), 728 (s).

**Synthesis of Cu2(pbpta).** A mixture of the ligand H4pbpta (7 mg, 0.01 mmol) and Cu(NO3)2·2H2O (12 mg, 0.05 mmol) was dissolved in a 20 mL scintillation vial containing DMF (1.2 mL), EtOH (0.3 mL), and HNO3 (80 μL, 2.7 M). The reagents were sonicated in a sealed vial prior to being placed in an oven at 65 °C for 24 h to yield green parallelepiped crystals. Yield: 54.2%. FT-IR (cm\(^{-1}\)): ν = 3061 (w, br.), 1593 (m), 1545 (m), 1383 (s), 1178 (w), 1104 (w), 1015 (m), 863 (w), 817 (m), 784 (s).

**Cycloaddition Reactions of CO2 with Epoxides.** For a typical reaction, the oxide (25 mmol), Cu2(pbpta) (20 mg equals 25 mmol of Cu(II)), and n-Bu4NBBr (0.58 g, 1.8 mmol) were added to a Schlenk tube and continuously purged with dry CO2 at 1 atm while stirring at room temperature for 48 h. The progress of the reaction was monitored by \(^1\)H NMR. This procedure was followed using the same molar amounts for propylene, epichlorohydrin, allyl glycidyl ether, and 1,2-butylene oxide. Control experiments were carried out without Cu2(pbpta).

**Ideal Adsorbed Solution Theory (IAST) Adsorption Selectivity.** IAST adsorption selectivity was calculated following previously reported methods. Single component adsorption isotherms (at room temperature) for each adsorbate were first fitted to the dual site Langmuir–Freundlich (DSLF) model, and the obtained parameters were used to calculate the adsorption selectivity between two components. More details about the method and fitting parameters have been provided in the Supporting Information.

**Estimation of Isosteric Heats of Adsorption, Qst.** At first, the adsorption data were fitted using the virial-type equation:

\[
\ln p = \ln N + \left( \frac{1}{T} \right) \sum_{j=0}^{m} a_j N^j + \sum_{j=0}^{n} b_j N^j
\]

(1)

Here \( p \) is the pressure expressed in Torr, \( N \) is the amount of adsorbed gas in mmol/g, \( T \) is the temperature in K, and \( a_j \) and \( b_j \) are virial coefficients, and \( m, n \) represent the number of coefficients required to adequately describe the isotherms. Then the Clausius–Clapeyron eq 2 was

\[
Q_{st} = RT \frac{\partial \ln p}{\partial T}
\]

(2)

employed to calculate the enthalpies of CO2 adsorption. Combining eqs 1 and 2, the isosteric heat of adsorption can be calculated using the following equation:

\[
Q_{st} = -R \sum_{j=0}^{m} a_j N^j
\]

(3)

The fitting parameters of the virial model are given in Table S6, and the adsorption enthalpies (\( Q_{st} \)) with uptake are given in Figure 5d.

## Results and Discussion

**Synthesis and Characterization.** The molecule H4pbpta is similar to ligands reported by Gole et al., Cai et al., and Alezi et al., which are extended analogues of the molecules used to construct the partially interpenetrated NOTT-202. H4pbpta (Figure 1) was synthesized in high yields from the oxidation of its methylated precursor. A solvothermal reaction of Cu(NO3)2·2H2O and H4pbpta in a 5:1 molar ratio dissolved in an acidic mixture of ethanol/ DMF (v/v = 1:4) heated at 65 °C for 24 h afforded single crystals of Cu2(pbpta). The IR spectra of Cu2(pbpta) shows the characteristic bands of coordinated carboxylate groups at 1593 and 1178 cm\(^{-1}\) for asymmetric and symmetric stretches, respectively (Figure S1, Supporting Information). The asymmetric stretch is 89 cm\(^{-1}\) red-shifted from the protonated reactant H4pbpta.
Crystal Structure Analysis. Block-shaped crystals suitable for single crystal X-ray diffraction experiments were harvested, and analyses found that Cu₂(pbpta) crystallizes in the monoclinic C2/m space group with a cell volume of 29547.9 Å³. Unit cell parameters and structural factors are included in Table S1. The bulk phase of Cu₂(pbpta) was confirmed by powder X-ray diffraction (Figure S2). The framework consists of two Cu(II) centers arranged with four carboxylate ligands into a copper acetate motif or paddlewheel molecular building block (MBB) with water molecules coordinated in its axial positions. The average Cu–Cu separation is 2.645 ± 0.03 Å, the carboxylate Cu–O distance is 1.925 ± 0.03 Å, and the water Cu–O distance is 2.132 ± 0.21 Å. Selected bond distances and angles of Cu₂(pbpta) are listed in Tables S2 and S3. We give the molecular formula for the partially interpenetrated structure as \([\text{Cu}_2(\text{pbpta})(2\text{H}_2\text{O})]\cdot[\text{Cu}_2(\text{pbpta})-(2\text{H}_2\text{O})]_{0.5}\cdot[\text{Cu}_2(\text{pbpta})(2\text{H}_2\text{O})]_{0.25}\), where the first framework (1) is fully occupied, and the latter two are 50% (2) and 25% (3) occupied, respectively, as determined by the occupancy factors from refinement of the crystal data. Partially interpenetrated frameworks 2 and 3 occupy similar but shifted positions in the crystal structure and can be considered disorder positions of each other. The second framework, from either 2 or 3, generates 2' or 3' from the space group's symmetry operations, which are unlikely to coexist because these symmetry related frameworks come within van der Waals distances as shown in Figure S4. Interpenetration from 1 with either 2(2') or 3(3') is shown in Figure 2. Interactions from the interpenetration occur between the ligands of different frameworks where both π−π and CH–O are within the ranges of reported interactions49 (Figure S3). The topological analysis of the fully occupied framework and the interpenetrating frameworks gives NbO topology (nbo) when considering both the MBB and the ligand as 4-connected nodes.

Physical Property Measurements. The as-synthesized and solvent exchanged Cu₂(pbpta) displayed different thermograms from the TGA experiments. The as-synthesized material exhibited a near 50% mass loss up to 150 °C before it plateaued, whereas methanol exchanged Cu₂(pbpta) only lost 10% in mass, which can be accounted for by 2.5 molecules of methanol per molecular unit (without interpenetration), before the material began to decompose near 250 °C (Figure S5, Supporting Information). The material could not be directly activated for gas adsorption experiments by methanol exchange and evacuation. It required an additional exchange with liquid CO₂ before it was supercritically dried and then placed on an ASAP 2020 outgas port at 80 °C for 10 h at a pressure lower than 10 μm Hg. A nitrogen adsorption−desorption isotherm at 77 K was collected for Cu₂(pbpta) and resulted in a Type I adsorption profile, which indicates characteristics of microporous materials (Figure 3). The calculated Brunauer, Emmett and Teller (BET) accessible surface area and total pore volume were 2537 m²/g and 1.06 cm³/g, respectively. Pore size distribution was evaluated using the density functional theory model and found pores of width less than 15 Å. This value agrees well with pore size measurements from the crystal structure.

Natural Gas Adsorption Experiments. Low pressure gas adsorption experiments with components of natural gas were carried out on Cu₂(pbpta) at 273 and 298 K up to 810 mmHg of pressure. The isotherms are shown in Figure 4, and the maximum uptake capacities are listed in Table 1. From these data we were able to calculate the \(Q_{st}\) at zero and higher loadings using the virial method (Figure 5d). We observe that Cu₂(pbpta) preferentially adsors more CO₂, ethane, and ethylene than CH₄. This is also reflected in the calculated \(Q_{st}\) values showing lower methane values at all loading concentrations. As shown in Table 2, the high \(Q_{st}\) of CO₂ at zero

---

**Figure 1.** H₄pbpta ligand.

**Figure 2.** Non-interpenetrated and interpenetrated view along the z-axis.
loading of 27 kJ/mol in Cu₂(pbpta) is higher than MOF-5 (17 kJ/mol), UMCM-1 (12 kJ/mol), CuBTTri (21 kJ/mol), and ZJNU-54a (24.7 kJ/mol) but comparable to JUC-199 (29 kJ/mol), HKUST-1 (hydrated) (30 kJ/mol), and MIL-53(Cr) (32 kJ/mol). We attribute this high value of the heat of adsorption to the presence of unsaturated metal centers (UMCs) in the framework which show strong interactions with the quadrupole of CO₂ and a likely second interaction with the ligand’s pyridyl nitrogen atom, which possesses a lone pair of electrons.

To establish the separation capability of CO₂ over methane, the adsorption selectivity was determined using IAST calculations. The selectivity was estimated as a function of pressure at 298 K under 101 kPa at an equimolar composition, a general landfill gas feed composition for a CO₂/CH₄ mixture. The selectivity at 298 K was also determined for an equimolar (50:50) and an excess (1:99) composition for the CO₂/CH₄ and CO₂/C₂H₆ mixtures. As shown in Figure 5a, the adsorption selectivity for the CO₂/CH₄ increases with an increase in total pressure at 298 K for an equimolar binary mixture of the two gases and reaches an adsorption selectivity value of ~6, which is higher than many reported MOFs under same conditions and comparable to JUC-199 (~9) previously reported. The selectivity at 273 K for an equimolar mixture reaches ~11 and is ~8 for a 1:99 mixture of the two gases. The selectivity for an equimolar C₂H₆/CH₄ mixture is ~12 and for C₂H₆/CH₄ mixture is ~15 at 298 K, which is higher than FIR-7a-ht (~8.6 for C₂H₆/CH₄ mixture and ~14.6 and for C₂H₆/CH₄ mixture).

Figure 3. Nitrogen adsorption−desorption isotherm at 77 K. Inset shows the pore size distribution.

mixture at 1 bar and 298 K), MFM-202a (\(\sim 8\) for C\(_2\)H\(_4\)/CH\(_4\) mixture and \(\sim 10\) and for C\(_2\)H\(_6\)/CH\(_4\) mixture at 1 bar and 293 K) and comparable to UTSA-35a (\(\sim 10\) for C\(_2\)H\(_4\)/CH\(_4\) mixture and \(\sim 20\) for C\(_2\)H\(_6\)/CH\(_4\) mixture at 1 bar and 296 K). The selectivity values at 273 K for equimolar and excess (1:99) mixtures for these gases are provided in Figures S6−S8 in Supporting Information. The \(Q_{st}\) values at 1.0 mmol/g of gas was realized at 32, 25, and 16 kJ/mol, respectively, for C\(_2\)H\(_6\), C\(_2\)H\(_4\), and CH\(_4\). Again, these values are similar to MMF-202a and UTSA-35a at low coverage.60,61 The high selectivity values are in accordance with the adsorption isotherms for the single components and \(Q_{st}\) values. These results suggest that Cu\(_2\)(pbpta) is an efficient material for capture and effective separation of CO\(_2\) from methane.

Cycloadition of CO\(_2\) with Epoxide. Since it is likely that CO\(_2\) will be trapped in Cu\(_2\)(pbpta) after enriching methane, the presence of unsaturated metal centers have an added benefit to allow for selective heterogeneous catalysis of CO\(_2\) into value-added chemicals. Several MOFs have been employed as Lewis acid catalysts for the chemical conversion of CO\(_2\) with other reagents, but these reactions require demanding conditions, such as high pressure and high temperature.62−65 We have followed previous procedures to convert epoxides11 (Scheme 1) into cyclic carbonates using CO\(_2\) and present our results in

\[ \text{Scheme 1. General Reaction Scheme for Conversion of Epoxides to Corresponding Cyclic Carbonates} \]

Table 3. The Cu\(_2\)(pbpta) showed a very high catalytic efficiency for the cycloaddition of epichlorohydrin to form epichlorohydrin carbonate in 94.3% yield after 48 h. Also, for the conversion of propylene oxide to propylene carbonate, the yield was 89.8% after 48 h, comparable to that of various porous materials reported before.66−72,11,16 High catalytic activity was also observed for the conversion of other epoxides to form their corresponding carbonates in quantitative yield (Table 3) at ambient temperature over a 48 h period. A decrease in product

yield was observed when the epoxide reagent’s size was increased, and we attributed this decrease to slower diffusion of the analytes into the MOF through its fixed apertures.

 ■ CONCLUSION
In summary, we synthesized Cu₂(pbpta), the first case reported for a partially interpenetrated MOF exhibiting NbO topology. The solvothermal reaction was suitable to reproduce the partially interpenetrated material as observed by single crystal and powder X-ray diffraction studies. The Cu₂(pbpta) exhibits a high surface area of 2537 m²/g and adsorption selectivity for CO₂, ethane, and ethylene over methane. In addition, due to presence of high density of catalytically active sites, it serves as a highly efficient catalyst for conversion of CO₂ into cyclic carbonates at ambient conditions. Further work to understand the partial interpenetration of this MOF is under investigation.
